

## **Supplement S4: Normalization and succinate production**

CEF values tend to be larger for smaller networks. If the CEFs as such are used to find deletion targets for the production of a desired metabolite, the algorithm tends to minimize the network size, besides maximizing product formation. The algorithm thereby favors the deletion of reactions with a high reaction participation and this leads to a biased set of deletion targets as we show in a test case on triple reaction deletions for succinate production in yeast in Table S3. The use of CEFs as such leads to a different ranking of deletion targets, in which the top ranked solutions contain less pathways. Moreover, the predicted growth using CEFs was higher than wild-type growth in many cases, which seems unrealistic. These effects would be even more prominent for mutants with a higher number of knockouts. Concluding, as CEFs are not comparable across networks, normalization is necessary to obtain feasible flux predictions.

**Table S3.** Predicted succinate production for triple reaction deletions in *S. cerevisiae* using structural fluxes (StruFs) compared with control effective fluxes [9]. Glucose uptake is 1.

Growth is relative to the wild-type growth rate. CEF values are normalized *a posteriori* for the sake of comparison. Nmodes is the number of remaining modes after deletion of the three reactions.

StruFs Reaction Knockouts	StruF <sup>succ</sup>	Growth %	Nmodes	CEFs Reaction Knockouts	CEF <sup>succ</sup>	Growth %	Nmodes
